1 The global food system faces various endogenous and exogenous, 2 biotic and abiotic risk factors, including a rising human population, 3 higher population densities, price volatility and climate change. 4 Quantitative models play an important role in understanding food 5 systems' expected responses to shocks and stresses. Here, we 6 present a stylised mathematical model of a national-level food system 7 that incorporates domestic supply of a food commodity, international 8 trade, consumer demand, and food commodity price. We 9 derive a critical compound parameter signalling when domestic supply 10 will become unsustainable and the food system entirely dependent 11 on imports, which results in higher commodity prices, lower 12 consumer demand and lower inventory levels. Using Bayesian estimation, 13 we apply the dynamic food systems model to infer the sustainability 14 of the UK pork industry. We find that the UK pork industry is currently 15 sustainable but because the industry is dependent on imports to meet 16 demand, a decrease in self-sufficiency below 50% (current levels are 17 60–65%) would lead it close to the critical boundary 18 signalling its collapse. Our model provides a theoretical foundation 19 for future work to determine more complex causal drivers of food 20 system vulnerability.

food security | dynamic systems | Bayesian estimation | resilience

1 Food security is defined as “when all people at all times 2 have physical, social and economic access to sufficient, 3 safe and nutritious food to meet their dietary needs and preferences 4 for an active and healthy life” (1). The realisation 5 of food security depends on the three pillars of access, utilisation 6 and availability (2, 3), and therefore is an outcome 7 of coupled agricultural, ecological and sociological systems 8 (4–6). In recent years, the resilience of food systems has 9 become a priority area of research (7–10) as biotic and abiotic, 10 endogenous and exogenous demands on food systems grow, 11 and the deleterious effects food systems currently have on the 12 environment become more apparent (11, 12). The challenge of 13 meeting the requirements of food security is for food systems 14 to expand their production capacities while remaining resilient 15 to unpredictable perturbations and limiting their effects on 16 the environment, such as reducing waste (13).

17 Food systems research is inherently transdisciplinary (4, 14), 18 of which one strand is computational and mathematical modelling. One utility of quantitative modelling is the ability to 19 build and perturb realistic ‘systems models’ of food systems to 20 project important outcomes, such as future food production 21 levels, farmer profitability, environmental degradation, food 22 waste, and consumer behaviour (11, 15–19). The difficulty 23 in modelling food systems is their complexity, frequently resulting 24 in large models with tens to hundreds of parameters and variables (e.g. (11, 16)), which are challenging to analyse 25 and even more challenging to statistically estimate from noisy 26 real-world data (20). In contrast, a handful of authors

29 have used relatively simple, theoretical models that are more 30 amenable to formal analysis, and have fewer parameters to 31 estimate from data. For example, (17) link population dynamics 32 to food availability and international trade using a generalised logistic 33 model. Additionally, (21) recently reported that the global food system 34 is approaching a critical point 35 signalling collapse into an unsustainable regime by condensing the 36 multi-dimensional global food trade network into a bistable, 37 one-dimensional system (using the framework of (22)). Simple 38 models of coupled ecological, economic and agricultural 39 processes have also been investigated, such as to explain 40 the emergence of poverty traps, which have direct effects on 41 individuals' access to food (23).

42 While simplified models are less suitable for making exact 43 predictions of complex systems' outcomes, their tractability 44 makes them better placed to elicit causal explanations and 45 generate hypotheses of how systems work (24–26). These 46 *stylised* models are the backbones of scientific disciplines such 47 as ecology (27), evolutionary biology (28), epidemiology (29), 48 economics (30), and physics (31). For instance, stylised mathematical 49 models of brain networks, animal collectives, ecosystems 50 and cellular dynamics have been used to find the critical 51 points at which they show abrupt qualitative changes in their 52 behaviours (32, 33). Food systems research, however, lacks 53 such foundational models. Systems dynamics modelling has 54 coupled agricultural production, supply chains, consumer demand, 55 price and human decision-making, such as (34) and (20). However, systems dynamics models of commodity cycles

Significance Statement

Mathematical models help understand how food systems function and respond to threats. We present a national food system model that can be applied to any food commodity in any country. The model shows two types of behaviour: a case where the domestic industry is sustainable and can compete with imports, and a case where the domestic industry is unsustainable and the food system is completely reliant on imports. These behavioural modes are controlled by a single compound parameter that weighs the profitability and productivity of the domestic industry against the strength of international trade. The model is used to assess the sustainability of the UK pork industry.

CG conceptualised the paper, developed and analysed the model, wrote the computer code, analysed the data, and wrote the first draft of the manuscript; SP reviewed model development and contributed to writing and reviewing the manuscript; WHMJ reviewed and contributed to writing the manuscript; NL reviewed and contributed to writing the manuscript; FS reviewed and contributed to writing the manuscript; LMC attained funding, helped conceptualise the model and paper, and reviewed and contributed to writing the manuscript.

are frequently high dimensional, encoding multiple modes of behaviour that are not easily amenable to standard mathematical analysis. Gaining greater theoretical insight into the dynamics of food systems and food security would be aided by simpler models of coupled agri-food systems.

In this paper, we develop and analyse a stylised model of a food system inspired by the systems dynamics modelling of (34) and (20), yet simple enough to offer general theoretical results. We focus on modelling a national-level food system, where the effects of international trade on domestic production is examined. Like the stylised models used to understand the causal processes in evolution, epidemics, and ecological interactions, our approach necessarily ignores many important features of real food systems. Nonetheless, its relative simplicity allows us to elucidate the precise conditions under which different stable modes of behaviour important to food system security emerge in our system.

We apply our theoretical model to the case of the UK pork industry, a key contributor to the UK meat industry which currently employs 75,000 employees and is worth £1.25 billion (35). Historically, pig industries have been of much interest to economists and agronomists as one of the first investigations into business or ‘pork’ cycles (20, 34, 36–41)). Business cycles reflect the oscillations between commodity prices and supply, which have been posited to be the result of both endogenous (30) and exogenous mechanisms (42). Over the last 20 years, however, the size of the UK pig industry has decreased by approximately 50%, from 800,000 to approximately 400,000 sows, due to a combination of legislative, epidemiological, and trade-related issues (43, 44). Following the ban on sow gestation crates in 1999, as well as disease outbreaks in the early 2000s, imports of pig meat increased by 50% (45), exceeding domestic production. While domestic production has returned to accounting for around 60–65% of total supply (45), the UK pig industry is still at risk from high costs of production (46) and ‘opportunistic dealing’ within the pork supply chain favouring cheaper imports (47). The sustainability of the UK pig industry is, thus, a concern for UK food system resilience, particularly with the incipient threats of Brexit and the COVID-19 pandemic that are affecting international trade, labour availability, commodity prices, and consumer demand (48–50). We demonstrate how our food systems model can be used to infer the sustainability of the UK pork industry using Bayesian estimation, enabling us to quantify full uncertainty in parameter estimates.

Mathematical model

Our food system model is composed of coupled ordinary differential equations, with the state variables of capital, inventory, consumer demand, and price (Figure 1; see variable and parameter definitions in Table 1). While we focus on food commodities, the model’s generality means that it could be applied to other types of commodity. Capital represents a raw material used to gauge the viability of the domestic industry, which could represent, for instance, the number of animals in the breeding herd for meat industries (34) or the number of paddy fields in rice supply chains (51). Inventory is the stock of processed food commodity being investigated. Consumer demand represents the amount of inventory demanded per time unit by the population of consumers, and is dependent on the commodity price. The commodity price represents the

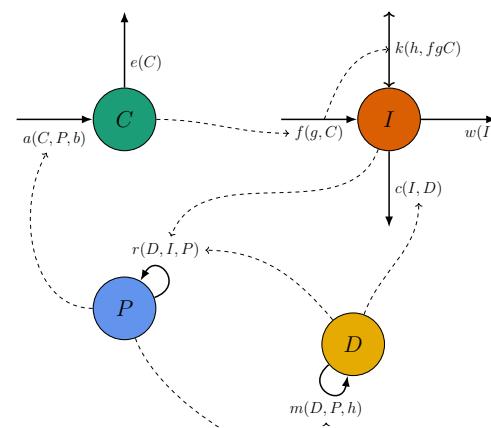

Fig. 1. The general structure of the theoretical complex food system model. Circles denote the the four state variables (capital, inventory, demand and price). Solid arrows indicate the different flows into and out of each state variable comprising their rate of change, and the arrow labels display generic functions of the model state variables and parameters (see Table 1 for the specific definitions used in this model). Dashed arrows show dependencies between different state variables and flows.

Symbol	Definition	Units

m	Demand response rate	[t ⁻¹]
q	Reference price	[PI ⁻¹]
r	Price growth rate	[t ⁻¹]

Table 1. Symbols, definitions and their units for the complex food system model.

price received by producers per unit of commodity produced, although we do not distinguish between producer and retail prices here (i.e. the producer price is assumed to be directly proportional to the retail price). While many of the mechanisms in supply chain functioning may be represented as a discrete-time system, we assume the aggregate behaviour of the national-level food system is adequately approximated in continuous time by a system of differential equations.

Capital changes according to the equation:

$$\frac{dC}{dt} = aC\left(\frac{P}{b} - 1\right) - eC \quad , \quad C(0) = C_0 \quad [1]$$

with initial condition at $t = 0$, C_0 . The parameter a is the rate of capital change (increase or decrease) depending on the

129 price to capital production cost (b) ratio. Capital depreciates
 130 at rate e , where e^{-1} is the average life-time of a capital unit.
 131 Inventory changes according to:

$$132 \frac{dI}{dt} = fgC - wI - \frac{I}{sD + I}D + k(h - fgC) , \quad I(0) = I_0 [2]$$

133 The first term represents the amount of inventory generated
 134 by domestic capital per time unit (i.e. domestic supply),
 135 where f is a production rate, and g is a conversion factor
 136 representing the amount of inventory units produced per unit
 137 of capital. Inventory is wasted (i.e. produced but not con-
 138 sumed) at rate w . The third term denotes the rate of inventory
 139 consumption by consumers, which is a non-linear Holling type-
 140 II/Michaelis-Menten function asymptoting at I for $D \gg I$.
 141 The dimensionless function $I/(sD + I)$ can be interpreted as
 142 the proportion of the demand that can be satisfied with the
 143 current inventory level. The parameter s is the ‘reference
 144 coverage’ converting inventory demanded per time unit into
 145 commodity units, and is interpreted as the number of time
 146 units-worth of inventory processors desire to have in stock.
 147 Perishable food commodities (e.g. meat) will have a lower ref-
 148 erence coverage, whereas less perishable items (e.g. rice, flour)
 149 can be stored for longer periods and, therefore, stock levels
 150 can be controlled by increasing s , lowering the proportion of
 151 demanded units satisfied.

152 The final term in equation 2 represents international trade,
 153 and its formulation can communicate different dynamics be-
 154 tween domestic producers, processors and retailers. We retain
 155 simplicity by assuming that trade is proportional to the dif-
 156 ference between a reference demand level (h) and current
 157 domestic production (fgC). When $h > fgC$, inventory is
 158 imported, and when $h < fgC$, inventory is exported. Realised
 159 demand (D) is a function of h and the current commodity
 160 price (see below), and therefore h represents the expected,
 161 baseline demand all else being equal (20). Trade levels adapt
 162 to the reference demand to avoid a positive feedback between
 163 higher prices, lower demand, and collapse of the commodity
 164 market for countries that are net importers, or a positive
 165 feedback between low prices, high demand, and exponentially
 166 increasing production for net exporters. In some industries,
 167 including the UK pork industry, cheaper international imports
 168 lower the domestic commodity price (52), and thus importing
 169 more than domestic supply when demand drops due to higher
 170 prices is a mechanism for lowering the commodity price and
 171 increasing demand. The difference between reference demand
 172 and domestic production that is traded, however, is limited
 173 by factors such as trade tariffs (49) or the ability of a nation
 174 to attract trade partners, and thus the parameter k controls
 175 the proportion of this difference. For countries that rely on
 176 international trade to supplement domestic supply to meet
 177 demand (net importers), $1 - k$ represents the self-sufficiency
 178 of the domestic industry (i.e. the percentage of total supplies
 179 produced domestically).

180 The instantaneous rate of change in demand is modelled
 181 as a simple function of reference demand and the commodity
 182 price to reference price ratio:

$$183 \frac{dD}{dt} = m\left(h \frac{q}{P} - D\right) , \quad D(0) = D_0 [3]$$

184 The parameter m controls the time-responsiveness of demand.
 185 The reference price q is typically interpreted as the price of

186 substitute items (20) or could represent consumers’ overall will-
 187 ingness to pay. When the current price exceeds the reference
 188 price, demand falls, and vice versa.

189 Many models exist for describing the price of commodities
 190 (e.g. see (53, 54) for some examples), and we adopt a relatively
 191 simple formulation here where the rate of change of price
 192 depends on the coverage:

$$193 \frac{dP}{dt} = rP\left(\frac{sD}{I} - 1\right) , \quad P(0) = P_0 [4]$$

194 The coverage is a dimensionless quantity representing the
 195 amount of commodity needed to sustain current demand for s
 196 time periods divided by the current inventory level. At rate
 197 given by r , the price increases when the coverage exceeds one,
 198 $sD/I > 1$, and decreases when coverage falls below 1.

199 To make our model more generalisable, we non-
 200 dimensionalise the system of equations above (see SI for non-
 201 dimensionalisation) using the dimensionless quantities in Table
 202 2, which reduces the number of parameters from 12 to 8. The
 203 non-dimensionalised system of equations is:

$$204 \begin{cases} \frac{dv}{d\tau} = v(\alpha z - 1) - \beta v \\ \frac{dx}{d\tau} = \delta v - \omega x - \gamma \frac{xy}{y+x} + \kappa(\gamma - \delta v) \\ \frac{dy}{d\tau} = \mu(z^{-1} - y) \\ \frac{dz}{d\tau} = \rho z(\frac{y}{x} - 1) \end{cases} [5]$$

205 where $\{v, x, y, z\}$ now represent the dimensionless state vari-
 206 ables, τ is rescaled time, and the dimensionless parameter
 207 groups are denoted by Greek letters.

Results

208 **Mathematical analysis.** No explicit solutions to the four-
 209 dimensional system of non-linear equations exist. Nonetheless,
 210 its dynamics can be summarised by investigating its stable
 211 modes of behaviour. To investigate stability, we conduct linear
 212 stability analyses (31). Linear stability analysis is based on a
 213 Taylor series expansion in multiple variables around the fixed
 214 points $(\hat{v}, \hat{x}, \hat{y}, \hat{z})$, where asymptotic (i.e. $t \rightarrow \infty$) stability
 215 to small perturbations can be inferred when the real part of
 216 the eigenvalues of the system’s matrix of partial derivatives
 217

(the Jacobian matrix representing the linearisation around the fixed points) evaluated at each equilibrium are negative. Notably, the inverse of the leading eigenvalue of the Jacobian matrix determines the ‘characteristic return time’ of the system, with more resilient systems returning more quickly to their equilibria following a disturbance (55).

Without international trade. When international trade is not present (i.e. $\kappa = 0$), there is one stable fixed point of the system given by the state variable values $\left\{ \frac{\alpha(2\omega+\gamma)}{2\delta(1+\beta)}, \frac{\alpha}{1+\beta}, \frac{\alpha}{1+\beta}, \frac{1+\beta}{\alpha} \right\}$. Another fixed point is where all state values are 0 (i.e. no industry). Conducting a linear stability analysis around the latter fixed point, the eigenvalues of the Jacobian matrix at this equilibria are $\{(-1 - \beta), -\omega, -\mu, -\rho\}$. All parameters are defined to be positive (except κ , which is 0 here), meaning there are no conditions where the ‘no industry’ equilibria will be stable when international trade is absent. In other words, the domestic industry is always viable.

With international trade. When $0 < \kappa < 1$, international trade is possible, opening the possibility of competition between domestic and international products, or of an export market for domestic production. An unstable equilibria still exists where all state variables are 0, except for $\hat{x} = \frac{\kappa\gamma}{\omega}$ because importing products is possible. However, in addition, there is 1) an unsustainable domestic production equilibrium, where the food system is entirely reliant on international imports, and 2) a sustainable domestic production equilibrium, where the domestic industry co-exists with international trade.

The unsustainable domestic supply equilibria is given by the set of fixed points $\{0, \frac{\kappa\gamma}{\omega+\frac{\gamma}{2}}, \frac{\kappa\gamma}{\omega+\frac{\gamma}{2}}, \frac{\omega+\frac{\gamma}{2}}{\kappa\gamma}\}$. By evaluating the sign of the eigenvalues of the Jacobian matrix evaluated at this equilibria (see SI), the unsustainable domestic supply equilibria is found to be stable if:

$$\text{critical ratio} = \frac{\alpha(\omega + \frac{\gamma}{2})}{\kappa\gamma(1 + \beta)} < 1 \quad [6]$$

The dependence of this critical ratio to changes in the original parameter values is shown in Figure 2a. The numerator represents a weighting of three factors: *i*) the *reference profitability* of capital production (α ; Table 2), *ii*) the *need for new commodity*, where either higher rates of waste or greater reference coverage increases the critical ratio, and *iii*) the *speed of capital production*, where higher rates (a in Table 1) increases the critical ratio (Figure 2a). By contrast, the denominator represents the *total strength* of international trade, which is composed of the trade strength parameter (κ), weighted by the viability of domestic capital: if the capital production rate increases, or capital depreciation rate decreases, the total trade strength becomes smaller, serving to increase the critical ratio.

When the critical ratio exceeds 1, the sustainable domestic production equilibrium is given by $\left\{ \frac{2\gamma\kappa(-1-\beta)+\alpha(\gamma+2\omega)}{2\delta(1+\beta)(1-\kappa)}, \frac{\alpha}{1+\beta}, \frac{\alpha}{1+\beta}, \frac{1+\beta}{\alpha} \right\}$. In the latter case, the equilibrium values of inventory, demand and price are the same as the equilibrium values of the model without international trade (see above), determined by the profitability of the domestic industry and the ratio of capital depreciation and growth rates. However, equilibrium inventory and demand are lower, and equilibrium price is higher, than when domestic supply is unsustainable. For example, the conditions

for equilibrium price when domestic supply is unsustainable to be higher than when domestic supply is sustainable (i.e. $\frac{\omega+\frac{\gamma}{2}}{\kappa\gamma} > \frac{1+\beta}{\alpha}$) is exactly the critical ratio. The latter trends are also seen the closer a system comes to the critical ratio. Thus, while international trade in the short term increases inventory levels, decreases the coverage (see model description) and, therefore, decreases the price and increases demand, the long-term result of the unsustainable domestic production regime is higher prices, lower demand and lower inventory levels.

The equilibrium value of capital is similar to the equilibrium value found in the model without international trade, but now factors in trade strength, κ (both equilibria are equal when $\kappa = 0$). Specifically, whether κ has a positive or negative influence on the long-term sustainable equilibrium domestic capital depends on whether the system is characterised by net imports (domestic supply is less than reference demand) or net exports (domestic supply exceeds reference demand), i.e. whether $\frac{\gamma}{\delta} - \hat{v}$ in equation 5 is greater than or less than zero. If domestic supply is less than reference demand, and the critical ratio exceeds 1, increasing trade strength will reduce the equilibrium value of capital in the long term limit (i.e. as $\tau \rightarrow \infty$). However, if domestic supply exceeds reference demand, increasing trade strength will increase the equilibrium capital due to a greater ability to export surplus product. From the previous inequality, we can define the surplus ratio, which signals that domestic supply will be greater than reference demand (net exports) if:

$$\text{surplus ratio} = \frac{\alpha(\omega + \frac{\gamma}{2})}{\gamma(1 + \beta)} \equiv \kappa \cdot \text{critical ratio} > 1 \quad [7]$$

which equals the critical ratio cancelling out the trade strength. Figures 2b-d demonstrate the relationship between the sustainable and unsustainable stable modes of behaviour in (κ, α) space for differing values of β , as well as the distinction between the sustainable state characterised by net imports or exports.

Application to UK pig industry. We estimated the parameters of the food systems model using Bayesian estimation from data available on the UK pig industry (see details in the Materials and methods). The critical ratio for the UK industry was estimated to be credibly above 1 (3), suggesting the industry is in a sustainable condition according to this model. The reference demand is estimated to be approximately 1.6 times that of the UK estimated pig meat annual consumption (approximately 140 million kg based off 25 kg/person/year and a population size of 66.65 million people; (56)). The trade strength is approximately 0.36 on average, which is consistent with the current self-sufficiency level of around 65% (i.e. around 35% of UK pig meat is imported). The difference between α and the surplus ratio is credibly less than zero (mean: -0.64; HDI: [-0.83, -0.43]), reflecting that UK production of pig meat does not meet expected demand. The critical κ value needed to push the UK domestic industry into the unsustainable regime is 0.61 (95% HDI: [0.56, 0.65]).

Posterior predictions (Figure 3) reflect the most plausible trajectories of the food system model generating the data, and posterior predictive distributions (open blue circles) cover a large proportion of the observed data. However, there are

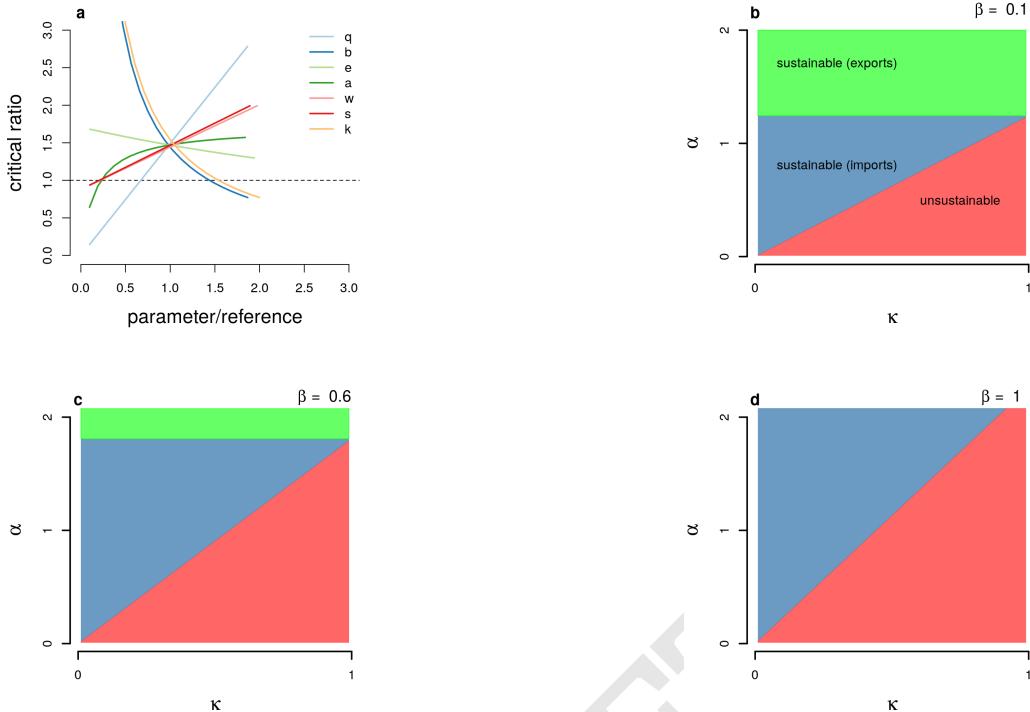

Fig. 2. Stability of the model incorporating international trade ($0 < \kappa < 1$). Panel a shows the sensitivity of the critical ratio to parameters in Table 1. The x-axis shows the ratio of the parameters to their reference values ($q = 160, b = 140, e = 0.033, a = 0.2, w = 0.33, s = 1, k = 0.5$). The horizontal dashed line shows the critical ratio threshold of unity. Panels b-d show the stable modes of behaviour in (κ, α) space for differing values of β , distinguishing between unsustainable (red), sustainable with imports (blue), and sustainable with exports (green) behaviours. Panels b-d are produced with the remaining parameters at $\gamma = 26, \omega = 10$ and $\delta = 5$.

Table 3. Key parameter estimates (mean and 95% highest density interval, HDI) and effective sample sizes (ESS) from fitting the model to the UK pig industry data. Parameters b and g were fixed at the constants 138.3 p/kg and 82.4 kg/pig, respectively.

only considers a simple international trade function (equation 2). We also note that the initial value for pork inventory (Figure 3c) is under-estimated.

Discussion

This paper has presented a theoretical model of a complex food system that balances analytical tractability and realism. The model represents the functioning of a national food system including international trade, and we have shown that the sustainability of the domestic industry depends on a critical compound parameter that comprises the profitability of the domestic industry (the reference price to cost of capital production ratio), the need for new commodity (commodity waste rates and reference coverage), the ability to produce new capital (capital growth and depreciation rates), and the strength of international trade (see Figure 2a). Below unity, this critical ratio signals that international trade out-competes the domestic industry and the model enters an unsustainable domestic supply regime characterised by complete reliance on imports. This unsustainable regime also results in higher equilibrium commodity prices, lower inventory and lower consumer demand than when domestic supply is sustainable. By estimating the key parameters of this ratio from data on real food systems, the sustainability of domestic industries, conditional on the assumptions of the model, can be evaluated.

Within the sustainable regime of the model, a key factor determining the long-term behaviour of the food system depends on whether it is characterised by net imports or net exports. In the context of the mathematical model, this is

additional sources of variation that the model trajectories do not account for. For instance, there is seasonal variation in UK pork production: the breeding herd tends to be higher in the July than in the December censuses (Figure 3a), resulting in higher UK production of pig meat (Figure 3e) in the latter portions of the year, likely in preparation for the Christmas period. The pig price is also more variable than the model can explain (Figure 3d), showing a notable drop in 2016 (corresponding to a fall in the EU pig price) and an increase in 2019. The difference between imports and exports (Figure 3f) fluctuated over the 2015–2019 time period, whereas the model

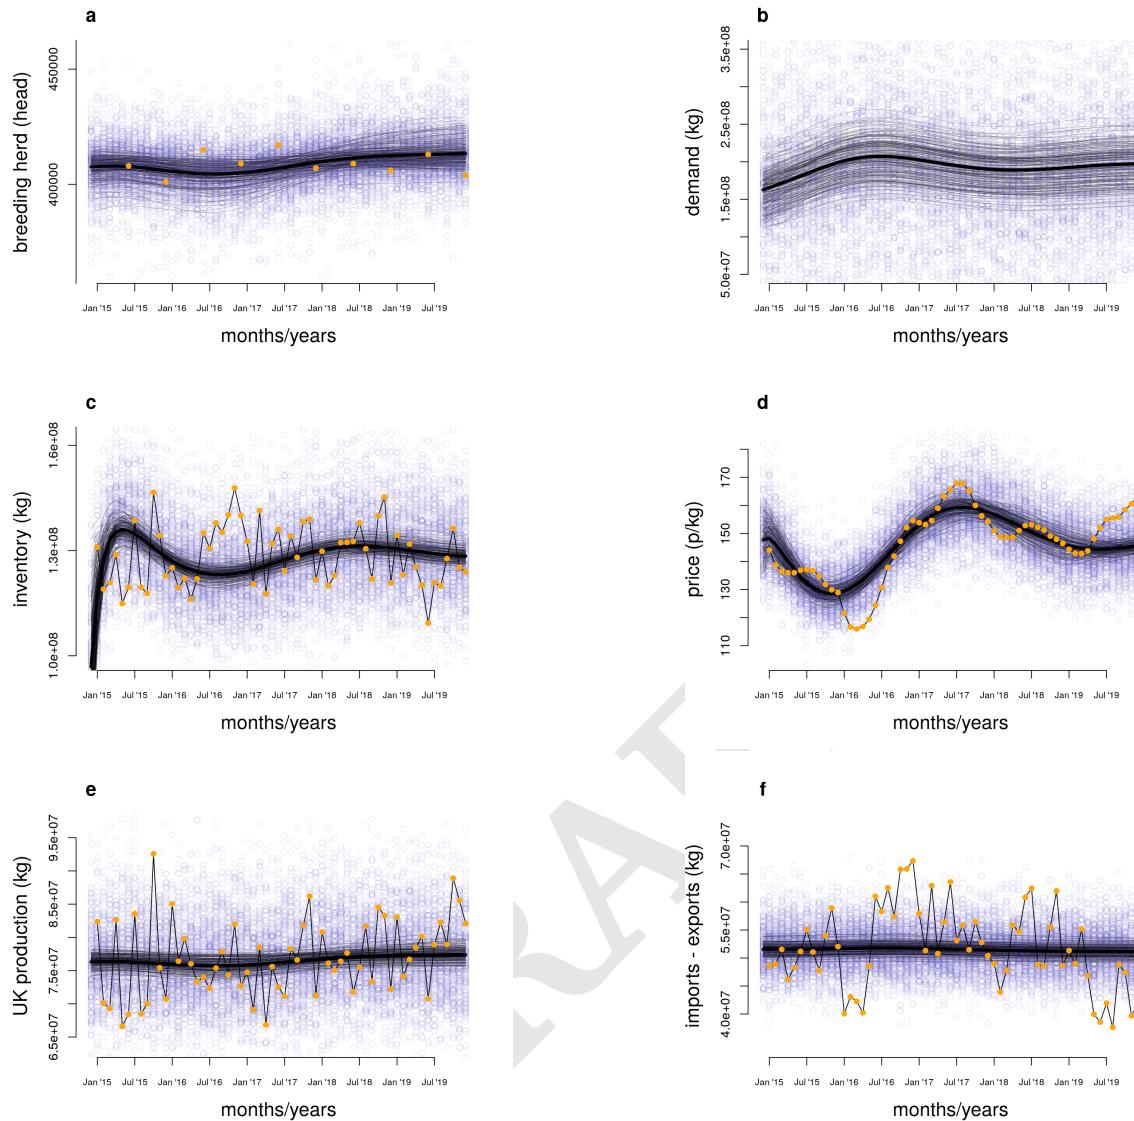

Fig. 3. Fitting the food systems model to the UK pig industry data. Orange filled circles show the raw monthly data (some data is missing), thin black lines display 200 random samples from the posterior distribution, the thick black lines indicate the mean posterior trajectory, and open blue circles display 200 random samples from the posterior predictive distribution (i.e. predictions incorporating random noise).

represented by whether the nation produces enough food to meet the reference demand (h in Table 1). We find that a food system that must supplement domestic supply with imports in order to meet demand (a net importer) is more vulnerable to collapse because increasing trade potential (higher k values) results in reduced self-sufficiency. Food systems that produce a surplus of domestic commodity can benefit from increased trade potential by exporting more (Figure 2), assuming that export markets are always available. This supports the current literature on the importance of diversifying food commodity sources to ensure food system resilience. Rapid globalisation has meant that 23% of the food produced globally, and 26% of global calorie production, is traded (21, 50, 57), and the majority of the world's diet is partly dependent on food imports (58) with several countries not producing enough food to satisfy basic, per-capita caloric intake (57). While global food trade has led to, and encourages further, diversification of

diets, it has also led to a less resilient global food system. This is because most countries in the trade network rely on imports from a smaller number of dominant trade partners (58), results supported also by theoretical modelling (21). The model here provides a critical boundary where a nation's food system may become entirely dependent on imports, leading to higher commodity prices, lower consumer demand and lower overall inventory levels. By the same token, complete self-sufficiency is an unrealistic and potentially harmful goal where the food system is again only reliant on a single supply chain (59).

Application of our model to 2015-2019 data from the UK pork industry demonstrated that the industry is in the sustainable model regime, with the critical ratio estimated credibly above 1 (Table 3). While the UK pork industry has diminished in size over the last 20 years (by around 50% since the late 1990s) its current level of self-sufficiency is around 60-65% and its export market continues to grow due to lower production

levels of the Chinese pork industry (e.g. (60)). The results from our model support this state of the industry: the ‘trade strength’ parameter (κ), which represents the proportion of the difference between reference demand levels and domestic production that can be traded, was estimated between 35 and 37%. Crucially, the critical value of κ that would tip the UK industry into collapse is estimated to be 61%, with a 95% highest density interval between 56 and 65%, suggesting if self-sufficiency drops below 50%, the industry will be closely approaching unsustainability. The UK food system faces a number of challenges in the coming years, including the impact of no-deal Brexit on trade tariffs allowing retailers easier access to cheaper imported meat (49), the continuing COVID-19 pandemic on the production and processing efficiency of food commodities (48), increasing popularity of reduced meat, vegetarian, vegan and plant-based diets on UK meat demand (61), and the potential for an African Swine Fever epidemic in the pig herd (62, 63). While under some scenarios, such as a bespoke Brexit trade deal with the EU, the price of pig meat might increase (49), representing a boost to domestic producers, our model indicates that this result is also consistent with a food system coming closer to the critical boundary delineating collapse (i.e. there is a negative relationship between long term price and the critical ratio) and, thus, might not be an advantage to the food system as a whole.

The mechanisms encoded in the model presented here are simple relative to the multi-factorial functioning of real food systems (5, 6). For instance, we have assumed that commodity prices respond only to changes in the supply-demand balance and not external factors such as global commodity prices and costs of production. Moreover, the model assumes that international trade responds only to the difference between reference demand and domestic production, and that exports of domestic produce are always available, ignoring how government regulations of trade flows may disrupt this scenario (e.g. pigmeat from pigs fed diets with feed additives such as ractopamine might fail government import regulations). Our specification that domestic capital changes proportional to the commodity price-production cost ratio (20) ignores heterogeneity in the structure of food supply chains. While similar assumptions have been used to build more complex system dynamics models (e.g. (20, 34)), there is great scope for expanding our system of differential equations to reveal the impact of, for instance, dis-aggregated actors of the supply chain (e.g. breeding pigs versus slaughter pigs, producers versus processors), the causal effects of non-financial drivers (e.g. preserving pig health and welfare) on supply chain functioning, heterogeneity in the production, demand and trade of different product types (e.g. fresh pork versus bacon and sausages), or how external factors, such as the climate, will influence production and demand (64). Nonetheless, our model provides a description of a single food system supported by both past theoretical and empirical work, and thus offers key insights into the conditions that promote sustainability of domestic food industries.

Materials and Methods

Data sources. A range of data are collected on the UK pork industry, but raw time series data is only available for certain variables and time frames. To fit our theoretical model, we focused on monthly

Variable	Data
t	Time set to monthly intervals between 2015 through 2019
C	Number of female pigs in the breeding herd (65)
I	Amount (kg) of new pork available for consumption (45, 66)
D	No data available
P	All pig price (kg/deadweight) (67)

Table 4. UK pork industry data sources used to fit the food systems model. All data available at <https://github.com/cmgoold/cfs-model/tree/master/data>.

data over a period of 5 years from 2015 through 2019, which covers the available annual data for the ‘All pig price’ per kilogram of dead-weight (i.e. a combined price for standard and premium pigs). All data sources used to fit the model are presented in Table 4. Monthly data for the inventory of pork, taking into account current levels of consumption and waste (e.g. the amount held in cold storage), is not reported in the UK. However, as an approximation, we used the total new monthly supplies, calculated as domestic production of pig meat plus imported pig meat minus exported pig meat. No data is available on consumer demand, as this is a theoretical quantity. Missing data was considered missing completely at random (i.e. ignorable) because data collection schemes are largely independent and fixed. For instance, there was no theoretical evidence that missing breeding herd data were dependent on the price or new supplies data.

Bayesian estimation. The parameters and initial conditions of the non-dimensionalised model were estimated using Bayesian estimation in the probabilistic programming language Stan (68) using the RStan interface in R (69, 70) using Stan’s Runge-Kutta 4th and 5th order integration scheme (see Stan code in the supplementary materials). The available monthly time series data, Y , for month i and state variable j was assumed log-normal distributed (to ensure positivity):

$$Y_i^j \sim \text{Lognormal}(\ln(Z^j), \sigma^j) \quad [8]$$

where Z^j is the state variable computed from the food systems model. In addition to fitting the state variables of the model to the time series data, we fit the UK monthly production figures, and the monthly imports and exports, to the respective flows from the model:

$$\text{Production} \sim \text{Lognormal}(\ln(fgZ^1), \epsilon_1) \quad [9]$$

$$\text{Imports} \sim \text{Lognormal}(\ln(kh), \epsilon_2) \quad [10]$$

$$\text{Exports} \sim \text{Lognormal}(\ln(kfgZ^1), \epsilon_3) \quad [11]$$

To aid computation, all parameters were transformed to a similar scale and given standard unit normal prior distributions (see full model specification in the supplementary materials), and were back-transformed to the appropriate scale when integrating the model. We did not estimate the parameters b (cost of capital production) and g (conversion factor from capital to inventory units) because these were known with enough certainty beforehand: b was set to the 138.3 p/kg (the average cost of production between 2015 and 2020), and g was set to 82.4 kg/pig, reflecting the average slaughter weight of pigs (109.9kg) multiplied by a 0.75 dressing/carcase yield (75%) most recently reported by (56). We ran 4 Markov chain Monte Carlo (MCMC) chains consisting of 2,500 iterations of warmup and 2,500 iterations of sampling, providing 10,000 samples from the posterior distribution for inference. All chains ran without any divergent transitions, and all parameters had effective sample sizes $>> 1000$ and \hat{R} statistics (i.e. the Gelman-Rubin diagnostic) $0.99 < \hat{R} < 1.002$ indicating convergence. Each parameter is summarised by its mean and 95% highest density interval (HDI, the most 95% most likely values).
